Abstract

We describe an iterative procedure for optimizing policies, with guaranteed monotonic improvement. By making several approximations to the theoretically-justified procedure, we develop a practical algorithm, called Trust Region Policy Optimization (TRPO). This algorithm is similar to natural policy gradient methods and is effective for optimizing large nonlinear policies such as neural networks. Our experiments demonstrate its robust performance on a wide variety of tasks: learning simulated robotic swimming, hopping, and walking gaits; and playing Atari games using images of the screen as input. Despite its approximations that deviate from the theory, TRPO tends to give monotonic improvement, with little tuning of hyperparameters.

1 Introduction

Most algorithms for policy optimization can be classified into three broad categories: (1) policy iteration methods, which alternate between estimating the value function under the current policy and improving the policy (Bertsekas, 2005); (2) policy gradient methods, which use an estimator of the gradient of the expected return (total reward) obtained from sample trajectories (Peters & Schaal, 2008a) (and which, as we later discuss, have a close connection to policy iteration); and (3) derivative-free optimization methods, such as the cross-entropy method (CEM) and covariance matrix adaptation (CMA), which treat the return as a black box function to be optimized in terms of the policy parameters (Szita & Lörincz, 2006).

General derivative-free stochastic optimization methods such as CEM and CMA are preferred on many problems, because they achieve good results while being simple to understand and implement. For example, while

Tetris is a classic benchmark problem for approximate dynamic programming (ADP) methods, stochastic optimization methods are difficult to beat on this task (Gabillon et al., 2013). For continuous control problems, methods like CMA have been successful at learning control policies for challenging tasks like locomotion when provided with hand-engineered policy classes with low-dimensional parameterizations (Wampler & Popović, 2009). The inability of ADP and gradient-based methods to consistently beat gradient-free random search is unsatisfying, since gradient-based optimization algorithms enjoy much better sample complexity guarantees than gradient-free methods (Nemirovski, 2005). Continuous gradient-based optimization has been very successful at learning function approximators for supervised learning tasks with huge numbers of parameters, and extending their success to reinforcement learning would allow for efficient training of complex and powerful policies.

In this article, we first prove that minimizing a certain surrogate objective function guarantees policy improvement with non-trivial step sizes. Then we make a series of approximations to the theoretically-justified algorithm, yielding a practical algorithm, which we call trust region policy optimization (TRPO). We describe two variants of this algorithm: first, the *single-path* method, which can be applied in the model-free setting; second, the *vine* method, which requires the system to be restored to particular states, which is typically only possible in simulation. These algorithms are scalable and can optimize nonlinear policies with tens of thousands of parameters, which have previously posed a major challenge for model-free policy search (Deisenroth et al., 2013). In our experiments, we show that the same TRPO methods can learn complex policies for swimming, hopping, and walking, as well as playing Atari games directly from raw images.

2 Preliminaries

Consider an **infinite-horizon discounted** Markov decision process (MDP), defined by the tuple $(\mathcal{S}, \mathcal{A}, P, r, \rho_0, \gamma)$, where \mathcal{S} is a **finite set of states**, \mathcal{A} is a **finite set of actions**, $P : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow \mathbb{R}$ is the transition probability distribution

bution, $r : \mathcal{S} \rightarrow \mathbb{R}$ is the reward function, $\rho_0 : \mathcal{S} \rightarrow \mathbb{R}$ is the distribution of the initial state s_0 , and $\gamma \in (0, 1)$ is the discount factor.

Let π denote a stochastic policy $\pi : \mathcal{S} \times \mathcal{A} \rightarrow [0, 1]$, and let $\eta(\pi)$ denote its expected discounted reward:

$$\eta(\pi) = \mathbb{E}_{s_0, a_0, \dots} \left[\sum_{t=0}^{\infty} \gamma^t r(s_t) \right], \text{ where}$$

$$s_0 \sim \rho_0(s_0), a_t \sim \pi(a_t | s_t), s_{t+1} \sim P(s_{t+1} | s_t, a_t).$$

We will use the following standard definitions of the state-action value function Q_π , the value function V_π , and the advantage function A_π :

$$Q_\pi(s_t, a_t) = \mathbb{E}_{s_{t+1}, a_{t+1}, \dots} \left[\sum_{l=0}^{\infty} \gamma^l r(s_{t+l}) \right],$$

$$V_\pi(s_t) = \mathbb{E}_{a_t, s_{t+1}, \dots} \left[\sum_{l=0}^{\infty} \gamma^l r(s_{t+l}) \right],$$

$$A_\pi(s, a) = Q_\pi(s, a) - V_\pi(s), \text{ where}$$

$$a_t \sim \pi(a_t | s_t), s_{t+1} \sim P(s_{t+1} | s_t, a_t) \text{ for } t \geq 0.$$

The following useful identity expresses the expected return of another policy $\tilde{\pi}$ in terms of the advantage over π , accumulated over timesteps (see Kakade & Langford (2002) or Appendix A for proof):

$$\eta(\tilde{\pi}) = \eta(\pi) + \mathbb{E}_{s_0, a_0, \dots \sim \tilde{\pi}} \left[\sum_{t=0}^{\infty} \gamma^t A_\pi(s_t, a_t) \right] \quad (1)$$

where the notation $\mathbb{E}_{s_0, a_0, \dots \sim \tilde{\pi}} [\dots]$ indicates that actions are sampled $a_t \sim \tilde{\pi}(\cdot | s_t)$. Let ρ_π be the (unnormalized) discounted visitation frequencies

$$\rho_\pi(s) = P(s_0 = s) + \gamma P(s_1 = s) + \gamma^2 P(s_2 = s) + \dots,$$

where $s_0 \sim \rho_0$ and the actions are chosen according to π . We can rewrite Equation (1) with a sum over states instead of timesteps:

$$\begin{aligned} \eta(\tilde{\pi}) &= \eta(\pi) + \sum_{t=0}^{\infty} \sum_s P(s_t = s | \tilde{\pi}) \sum_a \tilde{\pi}(a | s) \gamma^t A_\pi(s, a) \\ &= \eta(\pi) + \sum_s \sum_{t=0}^{\infty} \gamma^t P(s_t = s | \tilde{\pi}) \sum_a \tilde{\pi}(a | s) A_\pi(s, a) \\ &= \eta(\pi) + \sum_s \rho_{\tilde{\pi}}(s) \sum_a \tilde{\pi}(a | s) A_\pi(s, a). \end{aligned}$$

This equation implies that any policy update $\pi \rightarrow \tilde{\pi}$ that has a nonnegative expected advantage at every state s , i.e., $\sum_a \tilde{\pi}(a | s) A_\pi(s, a) \geq 0$, is guaranteed to increase the policy performance η , or leave it constant in the case that the expected advantage is zero everywhere. This implies the classic result that the update performed by exact policy iteration, which uses the deterministic policy

$\tilde{\pi}(s) = \arg \max_a A_\pi(s, a)$, improves the policy if there is at least one state-action pair with a positive advantage value and nonzero state visitation probability, otherwise the algorithm has converged to the optimal policy. However, in the approximate setting, it will typically be unavoidable, due to estimation and approximation error, that there will be some states s for which the expected advantage is negative, that is, $\sum_a \tilde{\pi}(a | s) A_\pi(s, a) < 0$. The complex dependency of $\rho_{\tilde{\pi}}(s)$ on $\tilde{\pi}$ makes Equation (2) difficult to optimize directly. Instead, we introduce the following local approximation to η :

$$L_\pi(\tilde{\pi}) = \eta(\pi) + \sum_s \rho_\pi(s) \sum_a \tilde{\pi}(a | s) A_\pi(s, a). \quad (3)$$

Note that L_π uses the visitation frequency ρ_π rather than $\rho_{\tilde{\pi}}$, ignoring changes in state visitation density due to changes in the policy. However, if we have a parameterized policy π_θ , where $\pi_\theta(a | s)$ is a differentiable function of the parameter vector θ , then L_π matches η to first order (see Kakade & Langford (2002)). That is, for any parameter value θ_0 ,

$$\begin{aligned} L_{\pi_{\theta_0}}(\pi_{\theta_0}) &= \eta(\pi_{\theta_0}), \\ \nabla_\theta L_{\pi_{\theta_0}}(\pi_\theta) \big|_{\theta=\theta_0} &= \nabla_\theta \eta(\pi_\theta) \big|_{\theta=\theta_0}. \end{aligned} \quad (4)$$

Equation (4) implies that a sufficiently small step $\pi_{\theta_0} \rightarrow \tilde{\pi}$ that improves $L_{\pi_{\theta_0}}$ will also improve η , but does not give us any guidance on how big of a step to take.

To address this issue, Kakade & Langford (2002) proposed a policy updating scheme called conservative policy iteration, for which they could provide explicit lower bounds on the improvement of η . To define the conservative policy iteration update, let π_{old} denote the current policy, and let $\pi' = \arg \max_{\pi'} L_{\pi_{\text{old}}}(\pi')$. The new policy π_{new} was defined to be the following mixture:

$$\pi_{\text{new}}(a | s) = (1 - \alpha) \pi_{\text{old}}(a | s) + \alpha \pi'(a | s). \quad (5)$$

Kakade and Langford derived the following lower bound:

$$\begin{aligned} \eta(\pi_{\text{new}}) &\geq L_{\pi_{\text{old}}}(\pi_{\text{new}}) - \frac{2\epsilon\gamma}{(1-\gamma)^2} \alpha^2 \\ \text{where } \epsilon &= \max_s |\mathbb{E}_{a \sim \pi'} [A_\pi(s, a)]|. \end{aligned} \quad (6)$$

(We have modified it to make it slightly weaker but simpler.) Note, however, that so far this bound only applies to mixture policies generated by Equation (5). This policy class is unwieldy and restrictive in practice, and it is desirable for a practical policy update scheme to be applicable to all general stochastic policy classes.

3 Monotonic Improvement Guarantee for General Stochastic Policies

Equation (6), which applies to conservative policy iteration, implies that a policy update that improves the right-hand

Sometimes doesn't always work (nonnegative + changing visitation frequency)

Combine old weights and new weights

exponential smoothing

These mathematical manipulation gives a "trust region" where any policy update can be trustworthy of not leading bad policy degradation

side is guaranteed to improve the true performance η . Our principal theoretical result is that the policy improvement bound in Equation (6) can be extended to general stochastic policies, rather than just mixture policies, by replacing α with a distance measure between π and $\tilde{\pi}$, and changing the constant ϵ appropriately. Since mixture policies are rarely used in practice, this result is crucial for extending the improvement guarantee to practical problems. The particular distance measure we use is the **total variation divergence**, ^{Distance btw two distributions} which is defined by $D_{TV}(p \parallel q) = \frac{1}{2} \sum_i |p_i - q_i|$ for discrete probability distributions p, q .¹ Define $D_{TV}^{\max}(\pi, \tilde{\pi})$ as

$$D_{TV}^{\max}(\pi, \tilde{\pi}) = \max_s D_{TV}(\pi(\cdot|s) \parallel \tilde{\pi}(\cdot|s)). \quad (7)$$

Theorem 1. Let $\alpha = D_{TV}^{\max}(\pi_{\text{old}}, \pi_{\text{new}})$. Then the following bound holds:

$$\eta(\pi_{\text{new}}) \geq L_{\pi_{\text{old}}}(\pi_{\text{new}}) - \frac{4\epsilon\gamma}{(1-\gamma)^2} \alpha^2$$

where $\epsilon = \max_{s,a} |A_{\pi}(s, a)|$ (8)

We provide two proofs in the appendix. The first proof extends Kakade and Langford's result using the fact that the random variables from two distributions with total variation divergence less than α can be coupled, so that they are equal with probability $1 - \alpha$. The second proof uses perturbation theory.

Next, we note the following relationship between the total variation divergence and the KL divergence (Pollard (2000), Ch. 3): $D_{TV}(p \parallel q)^2 \leq D_{KL}(p \parallel q)$. Let $D_{KL}^{\max}(\pi, \tilde{\pi}) = \max_s D_{KL}(\pi(\cdot|s) \parallel \tilde{\pi}(\cdot|s))$. The following bound then follows directly from Theorem 1

$$\eta(\tilde{\pi}) \geq L_{\pi}(\tilde{\pi}) - CD_{KL}^{\max}(\pi, \tilde{\pi}),$$

where $C = \frac{4\epsilon\gamma}{(1-\gamma)^2}$. (9)

Algorithm 1 describes an approximate policy iteration scheme based on the policy improvement bound in Equation (9). Note that for now, we assume exact evaluation of the advantage values A_{π} .

It follows from Equation (9) that Algorithm 1 is guaranteed to generate a monotonically improving sequence of policies $\eta(\pi_0) \leq \eta(\pi_1) \leq \eta(\pi_2) \leq \dots$. To see this, let $M_i(\pi) = L_{\pi_i}(\pi) - CD_{KL}^{\max}(\pi_i, \pi)$. Then

$$\begin{aligned} \eta(\pi_{i+1}) &\geq M_i(\pi_{i+1}) \text{ by Equation (9)} \\ \eta(\pi_i) &= M_i(\pi_i), \text{ therefore,} \\ \eta(\pi_{i+1}) - \eta(\pi_i) &\geq M_i(\pi_{i+1}) - M_i(\pi_i). \end{aligned} \quad (10)$$

Thus, by maximizing M_i at each iteration, we guarantee that the true objective η is non-decreasing. This algorithm

end for

is a type of minorization-maximization (MM) algorithm (Hunter & Lange, 2004), which is a class of methods that also includes expectation maximization. In the terminology of MM algorithms, M_i is the surrogate function that minorizes η with equality at π_i . This algorithm is also reminiscent of proximal gradient methods and mirror descent.

Trust region policy optimization, which we propose in the following section, is an approximation to Algorithm 1, which uses a constraint on the KL divergence rather than a penalty to robustly allow large updates.

4 Optimization of Parameterized Policies

In the previous section, we considered the policy optimization problem independently of the parameterization of π and under the assumption that the policy can be evaluated at all states. We now describe how to derive a practical algorithm from these theoretical foundations, under finite sample counts and arbitrary parameterizations.

Since we consider parameterized policies $\pi_{\theta}(a|s)$ with parameter vector θ , we will overload our previous notation to use functions of θ rather than π , e.g. $\eta(\theta) := \eta(\pi_{\theta})$, $L_{\theta}(\tilde{\theta}) := L_{\pi_{\theta}}(\pi_{\tilde{\theta}})$, and $D_{KL}(\theta \parallel \tilde{\theta}) := D_{KL}(\pi_{\theta} \parallel \pi_{\tilde{\theta}})$. We will use θ_{old} to denote the previous policy parameters that we want to improve upon.

The preceding section showed that $\eta(\theta) \geq L_{\theta_{\text{old}}}(\theta) - CD_{KL}^{\max}(\theta_{\text{old}}, \theta)$, with equality at $\theta = \theta_{\text{old}}$. Thus, by performing the following maximization, we are guaranteed to improve the true objective η :

$$\underset{\theta}{\text{maximize}} [L_{\theta_{\text{old}}}(\theta) - CD_{KL}^{\max}(\theta_{\text{old}}, \theta)].$$

In practice, if we used the penalty coefficient C recommended by the theory above, the step sizes would be very small. One way to take larger steps in a robust way is to use a constraint on the KL divergence between the new policy and the old policy, i.e., a trust region constraint:

$$\begin{aligned} &\underset{\theta}{\text{maximize}} L_{\theta_{\text{old}}}(\theta) \\ &\text{subject to } D_{KL}^{\max}(\theta_{\text{old}}, \theta) \leq \delta. \end{aligned} \quad (11)$$

¹Our result is straightforward to extend to continuous states and actions by replacing the sums with integrals.

Surrogate function

$$\eta(\pi) \geq L_{\pi}(\pi) - CD_{KL}^{\text{max}}(\pi, \pi_i)$$

$$\text{where } C = \frac{4\epsilon\gamma}{(1-\gamma)^2} \quad (9)$$

← maximizing surrogate function for each iteration guarantees that the true objective will be non decreasing

This problem imposes a constraint that the KL divergence is bounded at every point in the state space. While it is motivated by the theory, this problem is impractical to solve due to the large number of constraints. Instead, we can use a heuristic approximation which considers the average KL divergence:

$$\bar{D}_{\text{KL}}^{\rho}(\theta_1, \theta_2) := \mathbb{E}_{s \sim \rho} [D_{\text{KL}}(\pi_{\theta_1}(\cdot|s) \parallel \pi_{\theta_2}(\cdot|s))].$$

We therefore propose solving the following optimization problem to generate a policy update:

$$\begin{aligned} & \underset{\theta}{\text{maximize}} \quad L_{\theta_{\text{old}}}(\theta) \\ & \text{subject to} \quad \bar{D}_{\text{KL}}^{\rho_{\theta_{\text{old}}}}(\theta_{\text{old}}, \theta) \leq \delta. \end{aligned} \quad (12)$$

Similar policy updates have been proposed in prior work (Bagnell & Schneider 2003; Peters & Schaal 2008b; Peters et al. 2010), and we compare our approach to prior methods in Section 7 and in the experiments in Section 8. Our experiments also show that this type of constrained update has similar empirical performance to the maximum KL divergence constraint in Equation 11.

5 Sample-Based Estimation of the Objective and Constraint

The previous section proposed a constrained optimization problem on the policy parameters (Equation 12), which optimizes an estimate of the expected total reward η subject to a constraint on the change in the policy at each update. This section describes how the objective and constraint functions can be approximated using Monte Carlo simulation.

We seek to solve the following optimization problem, obtained by expanding $L_{\theta_{\text{old}}}$ in Equation 12:

$$\begin{aligned} & \underset{\theta}{\text{maximize}} \quad \sum_s \rho_{\theta_{\text{old}}}(s) \sum_a \pi_{\theta}(a|s) A_{\theta_{\text{old}}}(s, a) \\ & \text{subject to} \quad \bar{D}_{\text{KL}}^{\rho_{\theta_{\text{old}}}}(\theta_{\text{old}}, \theta) \leq \delta. \end{aligned} \quad (13)$$

We first replace $\sum_s \rho_{\theta_{\text{old}}}(s) [\dots]$ in the objective by the expectation $\frac{1}{1-\gamma} \mathbb{E}_{s \sim \rho_{\theta_{\text{old}}}} [\dots]$. Next, we replace the advantage values $A_{\theta_{\text{old}}}$ by the Q -values $Q_{\theta_{\text{old}}}$ in Equation 13, which only changes the objective by a constant. Last, we replace the sum over the actions by an importance sampling estimator. Using q to denote the sampling distribution, the contribution of a single s_n to the loss function is

$$\sum_a \pi_{\theta}(a|s_n) A_{\theta_{\text{old}}}(s_n, a) = \mathbb{E}_{a \sim q} \left[\frac{\pi_{\theta}(a|s_n)}{q(a|s_n)} A_{\theta_{\text{old}}}(s_n, a) \right].$$

Our optimization problem in Equation 13 is exactly equivalent to the following one, written in terms of expectations:

$$\begin{aligned} & \underset{\theta}{\text{maximize}} \quad \mathbb{E}_{s \sim \rho_{\theta_{\text{old}}}, a \sim q} \left[\frac{\pi_{\theta}(a|s)}{q(a|s)} Q_{\theta_{\text{old}}}(s, a) \right] \\ & \text{subject to} \quad \mathbb{E}_{s \sim \rho_{\theta_{\text{old}}}} [D_{\text{KL}}(\pi_{\theta_{\text{old}}}(\cdot|s) \parallel \pi_{\theta}(\cdot|s))] \leq \delta. \end{aligned} \quad (14)$$

Figure 1. Left: illustration of single path procedure. Here, we generate a set of trajectories via simulation of the policy and incorporate all state-action pairs (s_n, a_n) into the objective. Right: illustration of vine procedure. We generate a set of “trunk” trajectories, and then generate “branch” rollouts from a subset of the reached states. For each of these states s_n , we perform multiple actions (a_1 and a_2 here) and perform a rollout after each action, using common random numbers (CRN) to reduce the variance.

All that remains is to replace the expectations by sample averages and replace the Q value by an empirical estimate. The following sections describe two different schemes for performing this estimation.

The first sampling scheme, which we call *single path*, is the one that is typically used for policy gradient estimation (Bartlett & Baxter 2011), and is based on sampling individual trajectories. The second scheme, which we call *vine*, involves constructing a rollout set and then performing multiple actions from each state in the rollout set. This method has mostly been explored in the context of policy iteration methods (Lagoudakis & Parr 2003; Gabillon et al. 2013).

5.1 Single Path

In this estimation procedure, we collect a sequence of states by sampling $s_0 \sim \rho_0$ and then simulating the policy $\pi_{\theta_{\text{old}}}$ for some number of timesteps to generate a trajectory $s_0, a_0, s_1, a_1, \dots, s_{T-1}, a_{T-1}, s_T$. Hence, $q(a|s) = \pi_{\theta_{\text{old}}}(a|s)$. $Q_{\theta_{\text{old}}}(s, a)$ is computed at each state-action pair (s_t, a_t) by taking the discounted sum of future rewards along the trajectory.

5.2 Vine

In this estimation procedure, we first sample $s_0 \sim \rho_0$ and simulate the policy π_{θ_i} to generate a number of trajectories. We then choose a subset of N states along these trajectories, denoted s_1, s_2, \dots, s_N , which we call the “rollout set”. For each state s_n in the rollout set, we sample K actions according to $a_{n,k} \sim q(\cdot|s_n)$. Any choice of $q(\cdot|s_n)$ with a support that includes the support of $\pi_{\theta_i}(\cdot|s_n)$ will produce a consistent estimator. In practice, we found that $q(\cdot|s_n) = \pi_{\theta_i}(\cdot|s_n)$ works well on continuous problems, such as robotic locomotion, while the uniform distribution works well on discrete tasks, such as the Atari games, where it can sometimes achieve better exploration.

For each action $a_{n,k}$ sampled at each state s_n , we esti-

mate $\hat{Q}_{\theta_i}(s_n, a_{n,k})$ by performing a rollout (i.e., a short trajectory) starting with state s_n and action $a_{n,k}$. We can greatly reduce the variance of the Q -value differences between rollouts by using the same random number sequence for the noise in each of the K rollouts, i.e., *common random numbers*. See (Bertsekas 2005) for additional discussion on Monte Carlo estimation of Q -values and (Ng & Jordan 2000) for a discussion of common random numbers in reinforcement learning.

In small, finite action spaces, we can generate a rollout for every possible action from a given state. The contribution to $L_{\theta_{\text{old}}}$ from a single state s_n is as follows:

$$L_n(\theta) = \sum_{k=1}^K \pi_{\theta}(a_k | s_n) \hat{Q}(s_n, a_k), \quad (15)$$

where the action space is $\mathcal{A} = \{a_1, a_2, \dots, a_K\}$. In large or continuous state spaces, we can construct an estimator of the surrogate objective using importance sampling. The self-normalized estimator (Owen (2013), Chapter 9) of $L_{\theta_{\text{old}}}$ obtained at a single state s_n is

$$L_n(\theta) = \frac{\sum_{k=1}^K \frac{\pi_{\theta}(a_{n,k} | s_n)}{\pi_{\theta_{\text{old}}}(a_{n,k} | s_n)} \hat{Q}(s_n, a_{n,k})}{\sum_{k=1}^K \frac{\pi_{\theta}(a_{n,k} | s_n)}{\pi_{\theta_{\text{old}}}(a_{n,k} | s_n)}}, \quad (16)$$

assuming that we performed K actions $a_{n,1}, a_{n,2}, \dots, a_{n,K}$ from state s_n . This self-normalized estimator removes the need to use a baseline for the Q -values (note that the gradient is unchanged by adding a constant to the Q -values). Averaging over $s_n \sim \rho(\pi)$, we obtain an estimator for $L_{\theta_{\text{old}}}$, as well as its gradient.

The *vine* and *single path* methods are illustrated in Figure 1. We use the term *vine*, since the trajectories used for sampling can be likened to the stems of vines, which branch at various points (the rollout set) into several short offshoots (the rollout trajectories).

The benefit of the *vine* method over the *single path* method that is our local estimate of the objective has much lower variance given the same number of Q -value samples in the surrogate objective. That is, the *vine* method gives much better estimates of the advantage values. The downside of the *vine* method is that we must perform far more calls to the simulator for each of these advantage estimates. Furthermore, the *vine* method requires us to generate multiple trajectories from each state in the rollout set, which limits this algorithm to settings where the system can be reset to an arbitrary state. In contrast, the single path algorithm requires no state resets and can be directly implemented on a physical system (Peters & Schaal 2008b).

6 Practical Algorithm

Here we present two practical policy optimization algorithms based on the ideas above, which use either the *single path* or *vine* sampling scheme from the preceding section. The algorithms repeatedly perform the following steps:

1. Use the *single path* or *vine* procedures to collect a set of state-action pairs along with Monte Carlo estimates of their Q -values. *make a trajectory*
2. By averaging over samples, construct the estimated objective and constraint in Equation (14).
3. Approximately solve this constrained optimization problem to update the policy's parameter vector θ . We use the conjugate gradient algorithm followed by a line search, which is altogether only slightly more expensive than computing the gradient itself. See Appendix C for details.

With regard to (3), we construct the Fisher information matrix (FIM) by analytically computing the Hessian of the KL divergence, rather than using the covariance matrix of the gradients. That is, we estimate A_{ij} as $\frac{1}{N} \sum_{n=1}^N \frac{\partial^2}{\partial \theta_i \partial \theta_j} D_{\text{KL}}(\pi_{\theta_{\text{old}}}(\cdot | s_n) \| \pi_{\theta}(\cdot | s_n))$, rather than $\frac{1}{N} \sum_{n=1}^N \frac{\partial}{\partial \theta_i} \log \pi_{\theta}(a_n | s_n) \frac{\partial}{\partial \theta_j} \log \pi_{\theta}(a_n | s_n)$. The analytic estimator integrates over the action at each state s_n , and does not depend on the action a_n that was sampled. As described in Appendix C this analytic estimator has computational benefits in the large-scale setting, since it removes the need to store a dense Hessian or all policy gradients from a batch of trajectories. The rate of improvement in the policy is similar to the empirical FIM, as shown in the experiments.

Let us briefly summarize the relationship between the theory from Section 3 and the practical algorithm we have described:

- The theory justifies optimizing a surrogate objective with a penalty on KL divergence. However, the large penalty coefficient C leads to prohibitively small steps, so we would like to decrease this coefficient. Empirically, it is hard to robustly choose the penalty coefficient, so we use a hard constraint instead of a penalty, with parameter δ (the bound on KL divergence).
- The constraint on $D_{\text{KL}}^{\text{max}}(\theta_{\text{old}}, \theta)$ is hard for numerical optimization and estimation, so instead we constrain $\bar{D}_{\text{KL}}(\theta_{\text{old}}, \theta)$.
- Our theory ignores estimation error for the advantage function. (Kakade & Langford 2002) consider this error in their derivation, and the same arguments would hold in the setting of this paper, but we omit them for simplicity.

7 Connections with Prior Work

As mentioned in Section 4 our derivation results in a policy update that is related to several prior methods, providing a unifying perspective on a number of policy update

schemes. The natural policy gradient (Kakade, 2002) can be obtained as a special case of the update in Equation (12) by using a linear approximation to L and a quadratic approximation to the \bar{D}_{KL} constraint, resulting in the following problem:

$$\begin{aligned} & \text{maximize}_{\theta} \left[\nabla_{\theta} L_{\theta_{\text{old}}}(\theta) \Big|_{\theta=\theta_{\text{old}}} \cdot (\theta - \theta_{\text{old}}) \right] \\ & \text{subject to } \frac{1}{2} (\theta_{\text{old}} - \theta)^T A(\theta_{\text{old}}) (\theta_{\text{old}} - \theta) \leq \delta, \\ & \text{where } A(\theta_{\text{old}})_{ij} = \\ & \quad \frac{\partial}{\partial \theta_i} \frac{\partial}{\partial \theta_j} \mathbb{E}_{s \sim \rho_{\pi}} [D_{\text{KL}}(\pi(\cdot|s, \theta_{\text{old}}) \parallel \pi(\cdot|s, \theta))] \Big|_{\theta=\theta_{\text{old}}}. \end{aligned} \quad (17)$$

The update is $\theta_{\text{new}} = \theta_{\text{old}} + \frac{1}{\lambda} A(\theta_{\text{old}})^{-1} \nabla_{\theta} L(\theta) \Big|_{\theta=\theta_{\text{old}}}$, where the stepsize $\frac{1}{\lambda}$ is typically treated as an algorithm parameter. This differs from our approach, which enforces the constraint at each update. Though this difference might seem subtle, our experiments demonstrate that it significantly improves the algorithm’s performance on larger problems.

We can also obtain the standard policy gradient update by using an ℓ_2 constraint or penalty:

$$\begin{aligned} & \text{maximize}_{\theta} \left[\nabla_{\theta} L_{\theta_{\text{old}}}(\theta) \Big|_{\theta=\theta_{\text{old}}} \cdot (\theta - \theta_{\text{old}}) \right] \\ & \text{subject to } \frac{1}{2} \|\theta - \theta_{\text{old}}\|^2 \leq \delta. \end{aligned} \quad (18)$$

The policy iteration update can also be obtained by solving the unconstrained problem $\text{maximize}_{\pi} L_{\pi_{\text{old}}}(\pi)$, using L as defined in Equation (3).

Several other methods employ an update similar to Equation (12). *Relative entropy policy search* (REPS) (Peters et al., 2010) constrains the state-action marginals $p(s, a)$, while TRPO constrains the conditionals $p(a|s)$. Unlike REPS, our approach does not require a costly nonlinear optimization in the inner loop. Levine and Abbeel (2014) also use a KL divergence constraint, but its purpose is to encourage the policy not to stray from regions where the estimated dynamics model is valid, while we do not attempt to estimate the system dynamics explicitly. Pirota et al. (2013) also build on and generalize Kakade and Langford’s results, and they derive different algorithms from the ones here.

8 Experiments

We designed our experiments to investigate the following questions:

1. What are the performance characteristics of the *single path* and *vine* sampling procedures?
2. TRPO is related to prior methods (e.g. natural policy gradient) but makes several changes, most notably by using a fixed KL divergence rather than a fixed penalty coefficient. How does this affect the performance of the algorithm?

Figure 2. 2D robot models used for locomotion experiments. From left to right: swimmer, hopper, walker. The hopper and walker present a particular challenge, due to underactuation and contact discontinuities.

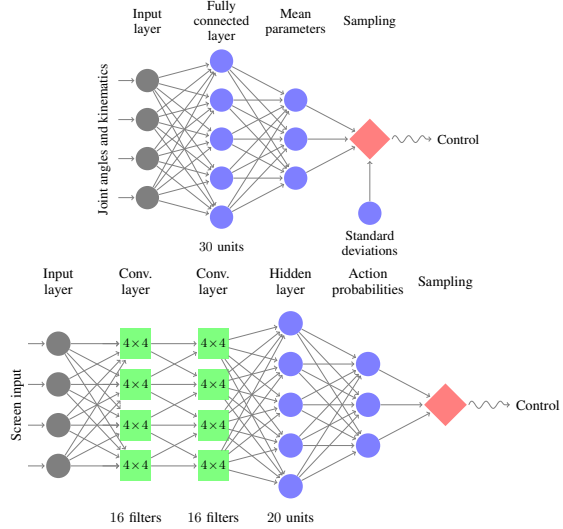

Figure 3. Neural networks used for the locomotion task (top) and for playing Atari games (bottom).

3. Can TRPO be used to solve challenging large-scale problems? How does TRPO compare with other methods when applied to large-scale problems, with regard to final performance, computation time, and sample complexity?

To answer (1) and (2), we compare the performance of the *single path* and *vine* variants of TRPO, several ablated variants, and a number of prior policy optimization algorithms. With regard to (3), we show that both the *single path* and *vine* algorithm can obtain high-quality locomotion controllers from scratch, which is considered to be a hard problem. We also show that these algorithms produce competitive results when learning policies for playing Atari games from images using convolutional neural networks with tens of thousands of parameters.

8.1 Simulated Robotic Locomotion

We conducted the robotic locomotion experiments using the MuJoCo simulator (Todorov et al., 2012). The three simulated robots are shown in Figure 2. The states of the robots are their generalized positions and velocities, and the controls are joint torques. Underactuation, high dimensionality, and non-smooth dynamics due to contacts make these

tasks very challenging. The following models are included in our evaluation:

1. *Swimmer*. 10-dimensional state space, linear reward for forward progress and a quadratic penalty on joint effort to produce the reward $r(x, u) = v_x - 10^{-5} \|u\|^2$. The swimmer can propel itself forward by making an undulating motion.
2. *Hopper*. 12-dimensional state space, same reward as the swimmer, with a bonus of +1 for being in a non-terminal state. We ended the episodes when the hopper fell over, which was defined by thresholds on the torso height and angle.
3. *Walker*. 18-dimensional state space. For the walker, we added a penalty for strong impacts of the feet against the ground to encourage a smooth walk rather than a hopping gait.

We used $\delta = 0.01$ for all experiments. See Table 2 in the Appendix for more details on the experimental setup and parameters used. We used neural networks to represent the policy, with the architecture shown in Figure 3 and further details provided in Appendix D. To establish a standard baseline, we also included the classic cart-pole balancing problem, based on the formulation from Barto et al. (1983), using a linear policy with six parameters that is easy to optimize with derivative-free black-box optimization methods.

The following algorithms were considered in the comparison: *single path TRPO*; *vine TRPO*; *cross-entropy method* (CEM), a gradient-free method (Szita & Lörincz, 2006); *covariance matrix adaptation* (CMA), another gradient-free method (Hansen & Ostermeier, 1996); *natural gradient*, the classic natural policy gradient algorithm (Kakade, 2002), which differs from *single path* by the use of a fixed penalty coefficient (Lagrange multiplier) instead of the KL divergence constraint; *empirical FIM*, identical to *single path*, except that the FIM is estimated using the covariance matrix of the gradients rather than the analytic estimate; *max KL*, which was only tractable on the cart-pole problem, and uses the maximum KL divergence in Equation (11), rather than the average divergence, allowing us to evaluate the quality of this approximation. The parameters used in the experiments are provided in Appendix E. For the *natural gradient* method, we swept through the possible values of the stepsize in factors of three, and took the best value according to the final performance.

Learning curves showing the total reward averaged across five runs of each algorithm are shown in Figure 4. *Single path* and *vine TRPO* solved all of the problems, yielding the best solutions. *Natural gradient* performed well on the two easier problems, but was unable to generate hopping and walking gaits that made forward progress. These results provide empirical evidence that constraining the KL divergence is a more robust way to choose step sizes and make fast, consistent progress, compared to using a fixed

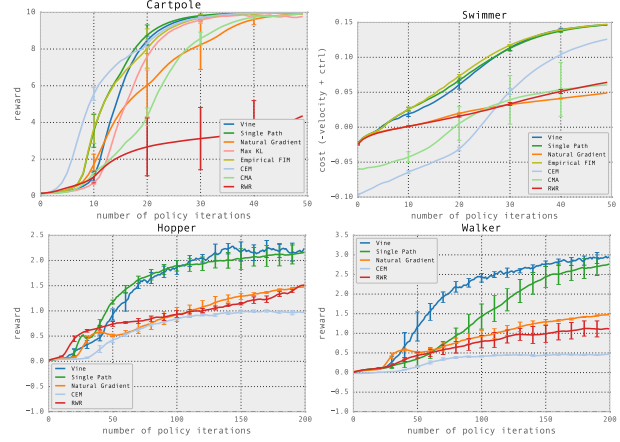

Figure 4. Learning curves for locomotion tasks, averaged across five runs of each algorithm with random initializations. Note that for the hopper and walker, a score of -1 is achievable without any forward velocity, indicating a policy that simply learned balanced standing, but not walking.

penalty. CEM and CMA are derivative-free algorithms, hence their sample complexity scales unfavorably with the number of parameters, and they performed poorly on the larger problems. The *max KL* method learned somewhat more slowly than our final method, due to the more restrictive form of the constraint, but overall the result suggests that the average KL divergence constraint has a similar effect as the theoretically justified maximum KL divergence. Videos of the policies learned by TRPO may be viewed on the project website: <http://sites.google.com/site/trpopaper/>

Note that TRPO learned all of the gaits with general-purpose policies and simple reward functions, using minimal prior knowledge. This is in contrast with most prior methods for learning locomotion, which typically rely on hand-architected policy classes that explicitly encode notions of balance and stepping (Tedrake et al., 2004; Geng et al., 2006; Wampller & Popović, 2009).

8.2 Playing Games from Images

To evaluate TRPO on a partially observed task with complex observations, we trained policies for playing Atari games, using raw images as input. The games require learning a variety of behaviors, such as dodging bullets and hitting balls with paddles. Aside from the high dimensionality, challenging elements of these games include delayed rewards (no immediate penalty is incurred when a life is lost in Breakout or Space Invaders); complex sequences of behavior (Q*bert requires a character to hop on 21 different platforms); and non-stationary image statistics (Enduro involves a changing and flickering background).

We tested our algorithms on the same seven games reported on in (Mnih et al., 2013) and (Guo et al., 2014), which are

	<i>B. Rider</i>	<i>Breakout</i>	<i>Enduro</i>	<i>Pong</i>	<i>Q*bert</i>	<i>Seaquest</i>	<i>S. Invaders</i>
Random	354	1.2	0	-20.4	157	110	179
Human (Mnih et al., 2013)	7456	31.0	368	-3.0	18900	28010	3690
Deep Q Learning (Mnih et al., 2013)	4092	168.0	470	20.0	1952	1705	581
UCC-I (Guo et al., 2014)	5702	380	741	21	20025	2995	692
TRPO - single path	1425.2	10.8	534.6	20.9	1973.5	1908.6	568.4
TRPO - vine	859.5	34.2	430.8	20.9	7732.5	788.4	450.2

Table 1. Performance comparison for vision-based RL algorithms on the Atari domain. Our algorithms (bottom rows) were run once on each task, with the same architecture and parameters. Performance varies substantially from run to run (with different random initializations of the policy), but we could not obtain error statistics due to time constraints.

made available through the Arcade Learning Environment (Bellemare et al., 2013). The images were preprocessed following the protocol in Mnih et al. (2013), and the policy was represented by the convolutional neural network shown in Figure 3, with two convolutional layers with 16 channels and stride 2, followed by one fully-connected layer with 20 units, yielding 33,500 parameters.

The results of the *vine* and *single path* algorithms are summarized in Table 1, which also includes an expert human performance and two recent methods: deep Q -learning (Mnih et al., 2013), and a combination of Monte-Carlo Tree Search with supervised training (Guo et al., 2014), called UCC-I. The 500 iterations of our algorithm took about 30 hours (with slight variation between games) on a 16-core computer. While our method only outperformed the prior methods on some of the games, it consistently achieved reasonable scores. Unlike the prior methods, our approach was not designed specifically for this task. The ability to apply the same policy search method to methods as diverse as robotic locomotion and image-based game playing demonstrates the generality of TRPO.

9 Discussion

We proposed and analyzed trust region methods for optimizing stochastic control policies. We proved monotonic improvement for an algorithm that repeatedly optimizes a local approximation to the expected return of the policy with a KL divergence penalty, and we showed that an approximation to this method that incorporates a KL divergence constraint achieves good empirical results on a range of challenging policy learning tasks, outperforming prior methods. Our analysis also provides a perspective that unifies policy gradient and policy iteration methods, and shows them to be special limiting cases of an algorithm that optimizes a certain objective subject to a trust region constraint.

In the domain of robotic locomotion, we successfully learned controllers for swimming, walking and hopping in a physics simulator, using general purpose neural networks and minimally informative rewards. To our knowledge, no prior work has learned controllers from scratch for all of these tasks, using a generic policy search method and non-engineered, general-purpose policy representations. In

the game-playing domain, we learned convolutional neural network policies that used raw images as inputs. This requires optimizing extremely high-dimensional policies, and only two prior methods report successful results on this task.

Since the method we proposed is scalable and has strong theoretical foundations, we hope that it will serve as a jumping-off point for future work on training large, rich function approximators for a range of challenging problems. At the intersection of the two experimental domains we explored, there is the possibility of learning robotic control policies that use vision and raw sensory data as input, providing a unified scheme for training robotic controllers that perform both perception and control. The use of more sophisticated policies, including recurrent policies with hidden state, could further make it possible to roll state estimation and control into the same policy in the partially-observed setting. By combining our method with model learning, it would also be possible to substantially reduce its sample complexity, making it applicable to real-world settings where samples are expensive.

Acknowledgements

We thank Emo Todorov and Yuval Tassa for providing the MuJoCo simulator; Bruno Scherrer, Tom Erez, Greg Wayne, and the anonymous ICML reviewers for insightful comments, and Vitchyr Pong and Shane Gu for pointing out errors in a previous version of the manuscript. This research was funded in part by the Office of Naval Research through a Young Investigator Award and under grant number N00014-11-1-0688, DARPA through a Young Faculty Award, by the Army Research Office through the MAST program.
